Abstract

Cell-free protein expression systems have become widely used in systems and synthetic biology. In this study, we developed an ensemble of dynamic *E. coli* cell-free protein synthesis (CFPS) models. Model parameters were estimated from measurements of glucose, organic acids, energy species, amino acids, and the protein product, chloramphenicol acetyltransferase (CAT). The ensemble described all of the training data, especially the central carbon metabolism. The model predicted a carbon yield for CAT production that was equal to 23% of the maximum theoretical yield, calculated using sequence-specific flux balance analysis. This suggests that CAT production could be further optimized. The dynamic modeling approach predicted that substrate consumption of glucose and pyruvate and oxidative phosphorylation were most important to both CAT production and the system as a whole, while CAT production alone depended heavily on the CAT synthesis reaction. Conversely, CAT production was robust to allosteric control, as was most of the network, with the exception of the organic acids in central carbon metabolism. This study is the first to model dynamic protein production in *E. coli*, and should provide a foundation for genome-scale, dynamic modeling of cell-free *E. coli* protein synthesis.

Keywords: Biochemical engineering, systems biology, cell-free protein synthesis

1 Introduction

2 Cell-free systems offer many advantages for the study, manipulation and modeling of
3 metabolism compared to *in vivo* processes. Central amongst these, is direct access to
4 metabolites and the biosynthetic machinery without the interference of a cell wall, or com-
5 plications associated with cell growth. This allows us to interrogate the chemical environ-
6 ment while the biosynthetic machinery is operating, potentially at a fine time resolution.
7 Cell-free protein synthesis (CFPS) systems are arguably the most prominent examples
8 of cell-free systems used today [1]. However, CFPS is not new; CFPS in crude *E. coli*
9 extracts has been used since the 1960s to explore fundamentally important biological
10 mechanisms [2, 3]. Today, cell-free systems are used in a variety of applications ranging
11 from therapeutic protein production [4] to synthetic biology [5, 6]. However, if CFPS is to
12 become a mainstream technology for applications such as point of care manufacturing,
13 we must first understand the performance limits of these systems. One tool to address
14 this question is mathematical modeling.

15 Mathematical modeling has long contributed to our understanding of metabolism. Dec-
16 ades before the genomics revolution, mechanistically structured metabolic models arose
17 from the desire to predict microbial phenotypes resulting from changes in intracellular
18 or extracellular states [7]. The single cell *E. coli* models of Shuler and coworkers pio-
19 neered the construction of large-scale, dynamic metabolic models that incorporated multi-
20 ple, regulated catabolic and anabolic pathways constrained by experimentally determined
21 kinetic parameters [8]. Shuler and coworkers generated many single cell kinetic mod-
22 els, including single cell models of eukaryotes [9, 10], minimal cell architectures [11], as
23 well as DNA sequence based whole-cell models of *E. coli* [12]. In the post genomics
24 world, large-scale stoichiometric reconstructions of microbial metabolism popularized by
25 techniques such as flux balance analysis (FBA) have become a standard approach [13].
26 Since the first genome-scale stoichiometric model of *E. coli*, developed by Edwards and

Palsson [14], well over 100 organisms, including industrially important prokaryotes are now available [15–17]. Stoichiometric models rely on a pseudo-steady-state assumption to reduce unidentifiable genome-scale kinetic models to an underdetermined linear algebraic system, which can be solved efficiently even for large systems. Traditionally, stoichiometric models have also neglected explicit descriptions of metabolic regulation and control mechanisms, instead opting to describe the choice of pathways by prescribing an objective function on metabolism. Interestingly, similar to early cybernetic models, the most common metabolic objective function has been the optimization of biomass formation [18], although other metabolic objectives have also been estimated [19]. Recent advances in constraint-based modeling have overcome the early shortcomings of the platform, including capturing metabolic regulation and control [20]. Thus, modern constraint-based approaches have proven extremely useful in the discovery of metabolic engineering strategies and represent the state of the art in metabolic modeling [21, 22]. However, genome-scale kinetic models of industrial important organisms such as *E. coli* have yet to be constructed.

In this study, we developed an ensemble of kinetic cell-free protein synthesis (CFPS) models using dynamic metabolite measurements in an *E. coli* cell free extract. Model parameters were estimated from measurements of glucose, organic acids, energy species, amino acids, and the protein product, chloramphenicol acetyltransferase (CAT). Characteristic values for model parameters and initial conditions, estimated from literature, were used to constrain the parameter estimation problem. The ensemble of parameter sets described the training data with a median cost that was greater than two orders of magnitude smaller than random sets constructed using the literature parameter constraints. We then used the ensemble of kinetic models to analyze the CFPS reaction. First, sensitivity analysis of the dynamic model suggested that CAT production was most sensitive to CAT synthesis parameters, as well as reactions in oxidative phosphorylation and pyruvate con-

sumption. Sensitivity analysis also showed that the system as a whole was most sensitive to these same parts of the network and glucose consumption. CAT production and other metabolites, specifically organic acid intermediates such as pyruvate, were sensitive to the presence of allosteric control mechanisms. Next, to gauge the performance of the cell-free reaction, we compared the observed CAT carbon yield with the maximum theoretical CAT carbon yield calculated using sequence-specific flux balance analysis. The CAT yield estimated from the kinetic model was 23% of the maximum theoretical yield, but 36% of the theoretical yield when physiologically realistic constraints were used. Taken together, we have integrated traditional kinetics with a logical rule-based description of allosteric control to simulate a comprehensive CFPS dataset. This study provides a foundation for genome-scale, dynamic modeling of cell-free *E. coli* protein synthesis.

Results

The ensemble of kinetic CFPS models captured the time evolution of CAT biosynthesis (Fig. 1 - 3). The cell-free *E. coli* metabolic network was constructed by removing growth associated reactions from the MG1655 reconstruction [23], and by adding reactions describing chloramphenicol acetyltransferase (CAT) biosynthesis, a model protein for which we have a comprehensive training dataset [24]. The CFPS model equations were formulated using the hybrid cell-free modeling framework of Wayman et al. [25]. An ensemble of model parameters ($N > 10,000$) was estimated from measurements of glucose, CAT, organic acids (pyruvate, lactate, acetate, succinate, malate), energy species (A(x)P, G(x)P, C(x)P, U(x)P), and 18 of the 20 proteinogenic amino acids using a constrained Markov Chain Monte Carlo (MCMC) approach. The MCMC algorithm minimized the error between the training data and model simulations starting from an initial parameter set assembled from literature and inspection. Parameter sets were selected for the ensemble based upon their error, and the Pearson correlation coefficient between the candidate and existing sets in the ensemble. The parameter set with the lowest error value was defined as the best-fit set. Central carbon metabolism (Fig. 1, top), energy species (Fig. 2), and amino acids (Fig. 3) were captured by the ensemble and the best-fit set. The constrained MCMC approach estimated parameter sets with a median error greater than two-order of magnitude less than random parameter sets generated within the same parameter bounds (Fig. 4); thus, we have confidence in the predictive capability of the estimated parameters. The model captures the biphasic nature of CFPS shown by the experimental data: in the first hour glucose consumption powers the system, and CAT is produced at $\sim 10 \mu\text{M/h}$; subsequently, pyruvate and lactate reserves are consumed to power metabolism, and CAT is produced less efficiently at $\sim 5 \mu\text{M/h}$. Allosteric control was important to this biphasic operation, as without it, both phases are sped up, and after 1.5 hours CAT synthesis has ceased (Fig. 1, bottom). In addition, acetate accumulation also

stops after 1.5 hours since there is no more substrate to power the system. Interestingly, malate captures the experimental measurements during the glucose consumption phase, but increases sharply during the pyruvate consumption phase.

While the model ensemble described the experimental data, it was unclear whether the performance of CFPS was optimal. To address this question, we used sequence-specific flux balance analysis in combination with a T7 promoter model to estimate the theoretical maximum performance of the system. We first validated the ssFBA approach by comparing simulated and measured concentrations of CAT for the first hour under glucose consumption (Fig. 7A). The ssFBA ensemble was able to predict the CAT dataset despite having no adjustable parameters. Uncertainty in experimental factors such as RNA polymerase, ribosome concentrations, elongation rates, or the upper bounds for oxygen and glucose consumption rates did not alter the qualitative performance of the model. Thus, the metabolic network and molecular description of transcription and translation were consistent with experimental measurements. To gauge the performance of CFPS, we next calculated the CAT carbon yield for three classes of constraints: (i) theoretical maximum glucose, amino acid and oxygen upper bounds, and no transcriptional/translational constraints; (ii) theoretical maximum glucose, amino acid and oxygen upper bounds, and realistic transcriptional/translational constraints; and (iii) metabolite fluxes constrained by the data, and realistic transcriptional/translational constraints (Fig. 7B). The unconstrained theoretical maximum CAT carbon yield (i) was 0.363 ± 0.02 (Fig. 7B, left); On the other hand, for realistic constraints on transcription and translation (ii), the CAT carbon yield was 0.226 ± 0.03 (Fig. 7B, middle). Lastly, when using realistic metabolite and transcription and translation constraints (iii), the predicted carbon yield was 0.062 ± 0.02 . By comparison, the best-fit parameter set had a CAT carbon yield of 0.086 ± 0.004 , equivalent to 23% of the theoretical maximum (i) and 36% of the physiological case (ii). The experimental dataset had a CAT carbon yield of 0.0821, similar to both the kinetic model and

the experimentally constrained case (iii).

To better understand which parameters and parameter combinations influenced model performance we performed sensitivity analysis (Fig. 5). According to the sensitivity results, CAT production was most dependent on coenzymes and pyruvate. CAT production was most sensitive to the CAT synthesis reaction, oxidative phosphorylation, and the pyruvate-consuming alanine synthesis reaction (Fig. 5, top, section A). Taking into account these three reactions as well as the next 16 most important reactions (section B), we see a common theme of reactions that involve the coenzymes ATP, GTP, NADH, and NADPH as well as the metabolites pyruvate and glutamate. Glutamate is important as a reagent for the synthesis of all other amino acids which are required to assemble the CAT protein. Meanwhile, the coenzymes are needed to provide energy to power the synthesis of CAT, and pyruvate becomes important for energy supply after glucose is exhausted. In addition, pyruvate is a key metabolite required for the synthesis of several amino acids. The pairwise sensitivities (off-diagonal elements) were different from the corresponding first-order sensitivities (diagonal elements), and led to interesting outcomes. The combination of certain reactions had a greater effect on CAT production than that of the reactions by themselves. For example, glutamine synthesis and arginine degradation were both among the most important reactions to CAT production (they rank 5th and 10th, respectively). This was likely because they both affect the sensitive glutamine-glutamate balance; glutamine synthesis consumes glutamate, while arginine degradation produces it. However, when both were perturbed, their combined effect on the model was low, as the respective contributions to consumption and production of glutamate cancelled.

The system state was also most dependent on coenzymes and substrates; however, instead of pyruvate and glutamate, the substrates driving metabolism were glucose and pyruvate. The metabolism as a whole was most sensitive to glucose uptake via GTP and the forward reaction of lactate dehydrogenase, consuming pyruvate (Fig. 5, bottom, sec-

tion F). These two and the next 30 most important reactions (section G) largely involved
coenzymes, especially ATP and NADPH, as well as substrate-consuming reactions and
oxidative phosphorylation. The system state had even more pairwise sensitivities that
differed from the corresponding first-order sensitivities and stood out as significant. For
example, the first-order effect of alanine synthesis was large; it consumes both pyruvate
and glutamate, two key species in the network. However, there were enough reactions
that, when paired with alanine synthesis, had little effect on the model; malic enzyme is
one of these, as it produces the pyruvate that alanine synthesis consumes. Thus, the
total-order alanine synthesis sensitivity was low, placing it at the very bottom of section I.
Another interesting result was the intersection of sections F and G with section J. The 53
reactions in section J were turned off in the best-fit set ($V^{max} = 0$); therefore, the pertur-
bation of these reactions had no effect on the model. As a result, all pairwise sensitivities
with reactions in section J were pseudo first-order sensitivities for the other reactions.
Interestingly, many reactions in section F and several in section G showed their highest
sensitivities when paired with the "non-effects" of section J. Of these, three involved pyru-
vate, strengthening its role as a key metabolite; the others were glucose consumption via
GTP/CTP-specific hexokinases, fumarate reductase, and SO_4 utilization. This suggested
that these reactions' effects on the model were canceled out or lessened by most other
reactions, but were of course not affected by the reactions in section J. This was also
likely the reason that reactions in section J rank above those in section K, despite having
no effect on the model themselves. Taken together, sensitivity analysis identified blocks
of parameters that either individually, or in combination influenced model performance.

The sensitivity analysis showed oxidative phosphorylation was significant for CAT pro-
duction as well as the system state. To further investigate this, we knocked out key re-
actions in oxidative phosphorylation to examine its effect on glucose uptake and CAT
production (Fig. 6). A single knockout of the reaction *cyd* was detrimental to model per-

168 formance and CAT production, reducing the CAT carbon yield from 8.6% to 2.8%. In
169 addition, the glucose uptake rate was reduced compared to that of the control (no knock-
170 outs). A knockout of *nuo* showed a less drastic effect, reducing the CAT carbon yield to
171 6.8%; however, the glucose uptake rate remained similar to that of the control. Knocking
172 out *app* showed a CAT yield to 8.8%, but was not statistically different from that of the con-
173 trol. With all three reactions knocked out, CAT yield was 2.7%, not statistically different
174 from the *cyd* knockout. Thus, the model suggests that the majority of the energetic needs
175 of the system as well as the production of CAT are met by oxidative phosphorylation,
176 specifically by *cyd*.

177 To investigate the difference in yields between the unconstrained and constrained
178 cases, we compared the flux distributions from the ssFBA simulations (Fig. 8). The con-
179 strained cases (ii & iii) heavily utilized the first step in the pentose phosphate pathway
180 to generate NADPH; the carbon flux continued through the Entner–Doudoroff pathway
181 toward pyruvate, a key metabolite as shown by sensitivity analysis. For case ii, the ma-
182 jority of the flux proceeded toward acetate accumulation, whereas in case iii, the flux
183 accumulated as pyruvate, lactate, and acetate with some going through the TCA cycle.
184 In comparison, the unconstrained case (i) showed the majority of flux traveling through
185 glycolysis towards pyruvate, leading to an accumulation of lactate, acetate and malate.
186 In all cases the energy source was primarily oxidative phosphorylation, and to a lesser
187 extent the TCA cycle. However, the accumulation of acetate and lactate signifies that the
188 system is not operating at its highest efficiency. The system produces NADH through
189 lactate dehydrogenase as well as through pyridine nucleotide transhydrogenase (*pntAB*)
190 to power oxidative phosphorylation. Oxidative phosphorylation leads to a high redox ra-
191 tio contributing to the accumulation of acetate overflow and diverting flux away from the
192 TCA cycle. This suggests that there is potential to increase CAT production by reducing
193 the accumulation of acetate and lactate. To investigate this further, we simulated poten-

194 tial knockouts with constrained transcription/translation rates, but constrained the specific
195 glucose and amino acid uptake rates to the same values as simulated with no knock-
196 outs. Knocking out the *gnd* reaction decreased flux of acetate production but increased
197 flux through *pntAB*, which is responsible for regenerating NADPH. The simulation showed
198 carbon was diverted toward lactate; however, since CAT production is constrained by the
199 translation rate, we expected no increase in CAT production. A second simulation with a
200 knockout of *gnd* and phosphate acetyltransferase showed carbon being diverted toward
201 lactate and succinate; however, it required a higher flux through oxidative phosphorylation
202 and the TCA cycle to meet the energetic needs of the system. The decrease in acetate
203 production and the diversion of carbon flux shows a promising mechanism to increase
204 CAT yield.

Discussion

In this study we present an ensemble of *E. coli* cell-free protein synthesis (CFPS) models that accurately predict a comprehensive CFPS dataset of glucose, CAT, central carbon metabolites, energy species, and amino acid measurements. We used the hybrid cell-free modeling approach of Wayman and coworkers, which integrates traditional kinetic modeling with a logic-based description of allosteric regulation. CFPS is seen to be biphasic relying on glucose during the first hour and pyruvate and lactate afterward. Allosteric control was essential to the maintenance of the network and production of CAT, as without it, central carbon metabolism is exhausted within 1.5 hours leading to low CAT production. Having captured the experimental data, we investigated if CAT yield and CFPS performance could be further improved. We showed that the model produces CAT at 23% of the theoretical maximum in terms of carbon yield, and at 36% of a physiological case in which transcription and translation are constrained. The accumulation of waste byproducts, especially acetate, is responsible for this sub-optimal yield. Sensitivity analysis showed that certain substrates and energy species are instrumental to CAT production and overall metabolism. The system heavily relied on oxidative phosphorylation for the system's energetic needs as well as for CAT synthesis. A single knockout in oxidative phosphorylation reduced the CAT carbon yield ~3-fold, as well as disrupting the system state showing its crucial role in CFPS. In comparing flux distributions between low and high yield cases, carbon flux could be potentially diverted toward CAT by reducing acetate overflow and minimizing flux through the Entner-Doudoroff pathway. Taken together, these findings represent the first dynamic model of *E. coli* cell-free protein synthesis, and an important step toward a functional genome scale description.

We present an ensemble of models that quantitatively describes the system behavior of cell-free metabolism and production of CAT. Experimental observations of the metabolites and cometabolites validate the structure of the model and the estimation of kinetic

parameters. This is important in applying metabolic engineering principles to rationally design cell-free production processes and predict the redirection of carbon fluxes to product forming pathways. In analyzing the model parameters' effect on CAT production, CAT synthesis is the most important, followed by oxidative phosphorylation and the glutamate and pyruvate consuming reactions, as well as coenzyme reactions which are necessary to drive CAT synthesis. For example, the conversion of ATP to GTP shows significance since it is necessary for CAT synthesis. While Jewett and coworkers have shown that ATP may be at saturation in CFPS [26], GTP is also required for CAT synthesis and may be a limiting reactant. Thus, supplementation with additional GTP may improve the efficiency of CAT production. A similar theme is seen in the sensitivity of overall model state, where the most important reactions are glucose and pyruvate consuming reactions and coenzyme reactions which are vital to drive CFPS. This can be seen in the biphasic operation of CFPS, with the first phase operating on glucose and the second phase operating on pyruvate. During the first phase, there is an accumulation of byproducts from central carbon with the majority of flux going toward acetate and some toward pyruvate, lactate, and succinate; with the exception of acetate, these are all consumed in the second phase. This shows that CAT production can be sustained by pyruvate and glutamate in the absence of glucose, which provides alternative strategies to optimize CFPS performance. This is in accordance with literature, which showed pyruvate provided a relatively slow but continuous supply of ATP [27]. Taken together, this shows CFPS can be designed towards a specified application either requiring a slow stable energy source or faster production. This outstanding control on model performance was expected as these metabolites are responsible for driving CFPS and represent the first step in the model network. Nevertheless, there are further reactions with considerable impact on model performance. In examining oxidative phosphorylation activity, knockouts in the electron transport pathways disrupt metabolism across the network and show CAT carbon yield dropping from

8.6% to 2.7%; Jewett and coworkers also saw a decrease in CAT yield, ranging from 1.5-fold to 4-fold, when knocking out oxidative phosphorylation reactions[26]. Oxidative phosphorylation is vital, since it provides most of the energetic needs of CFPS. However, it is unknown how active oxidative phosphorylation is compared to that of *in vivo* systems, and both of our modeling approaches suggest its importance to CAT production and CFPS. Thus, oxidative phosphorylation is a potential area for improvement for CFPS performance and protein yield. Comparing the theoretical maximum carbon yield of CAT from ssFBA predictions to those of the kinetic model and experimental measurements suggests that there is potential for increasing CAT yield as well as CFPS performance. The model and experimental yields were 36% of the theoretical maximum and 23% of a physiologically constrained case. Knockouts of *gnd* and phosphate acetyltransferase show that carbon can be diverted away from acetate and potentially toward CAT or other proteins of interest expressed in CFPS. Another limitation to be addressed in CFPS is the transcription and translation description, since protein production is ultimately bounded by these kinetic rates. Li et al. have increased productivity of firefly luciferase by 5-fold in CFPS systems by adding and adjusting factors that affect transcription and translation such as elongation factors, ribosome recycling factor, release factors, chaperones, BSA, and tRNAs [28]. Underwood and coworkers have also shown that an increase in ribosome levels does not significantly increase protein yields or rates; however, adding elongation factors increased yields by 23% at 30 minutes [29].

A logical next step for this work would be sequence-specific dynamic modeling, as the kinetic modeling approach in this study used a single reaction to approximate CAT synthesis. Including specific transcription and translation steps for CAT would allow more accurate modeling of the complexity and the resource cost of protein synthesis. In addition, sensitivity analysis could be performed on these new parameters to determine the robustness of CAT synthesis to the processes of transcription and translation. Another

area for future work is to more thoroughly sample parameter space. Parameters were varied so as to best fit the dataset; however, the resulting ensemble may not represent every biological possibility. In a different region of parameter space, the system may behave differently but still fit the experimental data. This could include the flux distribution through the network, the variation of predictions across the ensemble, and the relative sensitivity values. Testing the model under a variety of conditions could strengthen or challenge the findings of this study. Further experimentation could also be used to gain a deeper understanding of model performance under a variety of conditions. Specifically, CAT production performed in the absence of amino acids could inform the system's ability to manufacture them, while experimentation in the absence of glucose or oxygen could shed light on how important they are to protein synthesis, and under which conditions. Finally, the approach should be extended to other protein products. CAT is only a test protein used for model identification; the modeling framework, and to some extent the parameter values, should be protein agnostic. An important extension of this study would be to apply its insights to other protein applications, where possible.

Materials and Methods

Formulation and solution of the model equations. We used ordinary differential equations (ODEs) to model the time evolution of metabolite (x_i) and scaled enzyme abundance (ϵ_i) in hypothetical cell-free metabolic networks:

$$\frac{dx_i}{dt} = \sum_{j=1}^{\mathcal{R}} \sigma_{ij} r_j(\mathbf{x}, \epsilon, \mathbf{k}) \quad i = 1, 2, \dots, \mathcal{M} \quad (1)$$

$$\frac{d\epsilon_i}{dt} = -\lambda_i \epsilon_i \quad i = 1, 2, \dots, \mathcal{E} \quad (2)$$

where \mathcal{R} denotes the number of reactions, \mathcal{M} denotes the number of metabolites and \mathcal{E} denotes the number of enzymes in the model. The quantity $r_j(\mathbf{x}, \epsilon, \mathbf{k})$ denotes the rate of reaction j . Typically, reaction j is a non-linear function of metabolite and enzyme abundance, as well as unknown kinetic parameters \mathbf{k} ($\mathcal{K} \times 1$). The quantity σ_{ij} denotes the stoichiometric coefficient for species i in reaction j . If $\sigma_{ij} > 0$, metabolite i is produced by reaction j . Conversely, if $\sigma_{ij} < 0$, metabolite i is consumed by reaction j , while $\sigma_{ij} = 0$ indicates metabolite i is not connected with reaction j . Lastly, λ_i denotes the scaled enzyme activity decay constant. The system material balances were subject to the initial conditions $\mathbf{x}(t_o) = \mathbf{x}_o$ and $\epsilon(t_o) = 1$ (initially we have 100% cell-free enzyme abundance).

The reaction rate was written as the product of a kinetic term (\bar{r}_j) and a control term (v_j), $r_j(\mathbf{x}, \mathbf{k}) = \bar{r}_j v_j$. We used multiple saturation kinetics to model the reaction term \bar{r}_j :

$$\bar{r}_j = V_j^{max} \epsilon_i \prod_{s \in m_j^-} \frac{x_s}{K_{js} + x_s} \quad (3)$$

where V_j^{max} denotes the maximum rate for reaction j , ϵ_i denotes the scaled enzyme activity which catalyzes reaction j , K_{js} denotes the saturation constant for species s in reaction j and m_j^- denotes the set of *reactants* for reaction j . On the other hand, the control term $0 \leq v_j \leq 1$ depended upon the combination of factors which influenced

rate process j . For each rate, we used a rule-based approach to select from competing control factors. If rate j was influenced by $1, \dots, m$ factors, we modeled this relationship as $v_j = \mathcal{I}_j(f_{1j}(\cdot), \dots, f_{mj}(\cdot))$ where $0 \leq f_{ij}(\cdot) \leq 1$ denotes a transfer function quantifying the influence of factor i on rate j . The function $\mathcal{I}_j(\cdot)$ is an integration rule which maps the output of regulatory transfer functions into a control variable. We used hill-like transfer functions and $\mathcal{I}_j \in \{min, max\}$ in this study [25].

We included 17 allosteric regulation terms, taken from literature, in the CFPS model. PEP was modeled as an inhibitor for phosphofructokinase [30, 31], PEP carboxykinase [30], PEP synthetase [30, 32], isocitrate dehydrogenase [30, 33], and isocitrate lyase/malate synthase [30, 33, 34], and as an activator for fructose-biphosphatase [30, 35–37]. AKG was modeled as an inhibitor for citrate synthase [30, 38, 39] and isocitrate lyase/malate synthase [30, 34]. 3PG was modeled as an inhibitor for isocitrate lyase/malate synthase [30, 34]. FDP was modeled as an activator for pyruvate kinase [30, 40] and PEP carboxylase [30, 41]. Pyruvate was modeled as an inhibitor for pyruvate dehydrogenase [30, 42, 43] and as an activator for lactate dehydrogenase [44]. Acetyl CoA was modeled as an inhibitor for malate dehydrogenase [30].

Estimation of kinetic model parameters. We generated an ensemble of diverse parameter sets using a constrained Markov Chain Monte Carlo (MCMC) random walk strategy. Starting from a single best fit parameter set estimated by inspection and literature, we calculated the cost function, equal to the sum-squared-error between experimental data and model predictions:

$$\text{cost} = \sum_{i=1}^{\mathcal{D}} \left[\frac{w_i}{\mathcal{Y}_i^2} \sum_{j=1}^{\mathcal{T}_i} \left(y_{ij} - x_i|_{t(j)} \right)^2 \right] \quad (4)$$

where \mathcal{D} denotes the number of datasets ($\mathcal{D} = 37$), w_i denotes the weight of the i^{th} dataset, \mathcal{T}_i denotes the number of timepoints in the i^{th} dataset, $t(j)$ denotes the j^{th} time-

point, y_{ij} denotes the measurement value of the i^{th} dataset at the j^{th} timepoint, and $x_i|_{t(j)}$ denotes the simulated value of the metabolite corresponding to the i^{th} dataset, interpolated to the j^{th} timepoint. Lastly, the cost calculation was scaled by the maximum experimental value in the i^{th} dataset, $\mathcal{Y}_i = \max_j (y_{ij})$. We then perturbed each model parameter between an upper and lower bound that varied by parameter type:

$$k_i^{new} = \min(\max(k_i \cdot \exp(a \cdot r_i), l_i), u_i) \quad i = 1, 2, \dots, \mathcal{P} \quad (5)$$

where \mathcal{P} denotes the number of parameters ($\mathcal{P} = 815$), which includes 163 maximum reaction rates (V^{max}), 163 enzyme activity decay constants, 455 saturation constants (K_{js}), and 34 control parameters, k_i^{new} denotes the new value of the i^{th} parameter, k_i denotes the current value of the i^{th} parameter, a denotes a distribution variance, r_i denotes a random sample from the normal distribution, l_i denotes the lower bound for that parameter type, and u_i denotes the upper bound for that parameter type. Maximum reaction rates were bounded between 0 and 500,000 mM/h [45]. Assuming a total enzyme concentration of 50 μ M, this corresponds to catalytic rate bounds of 0 and 2778 s^{-1} . These bounds resulted in a median catalytic rate of 0.016 s^{-1} across the ensemble. Enzyme activity decay constants were bounded between 0 and 1 h^{-1} , corresponding to half lives of 42 minutes and infinity; median = 25 min. Saturation constants were bounded between 0.001 and 10 mM; median = 0.16 mM. Control parameters (gains and orders) were left unbounded; gain median = 0.076, order median = 0.69. For each newly generated parameter set, we re-solved the balance equations and calculated the cost function. All sets with a lower cost than the previous set, and some with higher cost, were added to the ensemble. After generating 12,437 sets, we selected 100 sets with minimal set to set correlation to avoid over-sampling any region of parameter space. The original 12,437-set ensemble had a mean Pearson correlation coefficient of 0.94 between pairs of sets, while the 100-set

ensemble had a mean Pearson correlation coefficient of 0.83 between pairs of sets.

Sensitivity analysis of the CFPS model. We determined the reactions most important to protein production by computing the local sensitivity of CAT concentration (denoted as CAT) to each individual maximum reaction rate, and each pair of maximum reaction rates in the network. The sensitivity index was formulated as:

$$S_{ij}^{\text{CAT}} = \|\text{CAT}(p_i, p_j, t) - \text{CAT}(\alpha \cdot p_i, \alpha \cdot p_j, t)\|_2 \quad i, j = 1, 2, \dots, \mathcal{P} \quad (6)$$

where S_{ij}^{CAT} denotes the sensitivity of CAT production to the i^{th} and j^{th} parameters, $\text{CAT}(p_i, p_j, t)$ denotes CAT concentration as a function of time and the i^{th} and j^{th} parameters, α denotes the perturbation factor, and \mathcal{P} denotes the number of maximum reaction rates ($\mathcal{P} = 163$). In calculating the pairwise sensitivities, each parameter was perturbed by 1%; first-order sensitivities ($i = j$) were subject to two 1% perturbations. Parameters and parameter combinations were categorized into five degrees of importance, from least to most sensitive. This was achieved by assigning them a value of 0, 0.25, 0.5, 0.75, or 1.

Likewise, we determined the reactions most important to global system performance by computing the sensitivity of all species for which data exists (denoted as \mathbf{X}) to each maximum reaction rate in the network. In this case, each sensitivity index was formulated as:

$$S_{ij}^{\mathbf{X}} = \|\mathbf{X}(p_i, p_j, t) - \mathbf{X}(\alpha \cdot p_i, \alpha \cdot p_j, t)\| \quad i, j = 1, 2, \dots, \mathcal{P} \quad (7)$$

where $S_{ij}^{\mathbf{X}}$ denotes the sensitivity of the system state to the i^{th} and j^{th} parameters, and $\mathbf{X}(p_i, p_j, t)$ denotes the system state, an array consisting of the concentration of every species for which data exists as a function of time and the i^{th} and j^{th} parameters. The parameter sensitivities were also categorized into five groups, as above.

Sequence-specific FBA and calculation of CAT yield The yield on CAT production was calculated for each case as a ratio of carbon produced as CAT to carbon consumed as reactants (glucose and amino acids):

$$Yield = \frac{\Delta m_{CAT} C_{CAT}}{\sum_{i=1}^{\mathcal{R}} \max(\Delta m_i, 0) C_{m_i}} \quad (8)$$

where Δm_{CAT} denotes the amount of CAT produced, C_{CAT} denotes carbon number of CAT, \mathcal{R} denotes the number of reactants, Δm_i denotes the amount of the i^{th} reactant consumed, never allowed to be negative, and C_{m_i} denotes the carbon number of the i^{th} reactant. Because no data was available for arginine or glutamate, these reactants were left out of all yield calculations. Yield of the best-fit parameter set and the experimental data were calculated by setting ΔCAT equal to the final minus the initial CAT concentration and setting Δm_i equal to the initial minus the final reactant concentration. Theoretical maximum CAT carbon yields for three cases discussed below were calculated using flux balance analysis (FBA) with a sequence-specific description of CAT synthesis, where Δm_i denotes the flux of the i^{th} species. This sequence-specific FBA [46] problem was formulated as:

$$\begin{aligned} & \max_{\mathbf{w}} (w_{obj} = \boldsymbol{\theta}^T \mathbf{w}) \\ & \text{Subject to : } \mathbf{S}\mathbf{w} = \mathbf{0} \\ & \alpha_i \leq w_i \leq \beta_i \quad i = 1, 2, \dots, \mathcal{R} \end{aligned} \quad (9)$$

where \mathbf{S} denotes the stoichiometric matrix, \mathbf{w} denotes the unknown flux vector, $\boldsymbol{\theta}$ denotes the objective selection vector and α_i and β_i denote the lower and upper bounds on flux w_i , respectively. The objective w_{obj} was to maximize the specific rate of CAT formation. The specific glucose uptake rate was constrained to allow a maximum flux of 40 mM/h according to experimental data; the specific amino acid uptake rates were bound to allow a maximum flux of 30 mM/h, but did not reach this maximum flux. The transcription and

translation template reactions come from sequence-specific analysis [46], and include transcription initiation, transcription, mRNA degradation, translation initiation, translation, and tRNA charging. The flux balance analysis problem was solved using the GNU Linear Programming Kit (v4.52) [47]. The solution flux vector was used to calculate the carbon yield of CAT for the three FBA cases. Glucose, oxygen, and amino acids were modeled as being imported into the system, while CAT synthesis and metabolite byproduct formation were modeled as export from the system. The rest of the network followed a pseudo steady-state assumption where metabolites were not allowed to accumulate; thus, the network could be solved by linear programming instead of solving differential equations.

The transcription rate was formulated as:

$$w_{TX} = RNAP \left(\frac{v_{RNAP}}{l_{mRNA}} \right) \left(\frac{Gene}{k_m + Gene} \right) P \quad (10)$$

where w_{TX} denotes the transcription rate, $RNAP$ denotes the concentration of RNA polymerase, v_{RNAP} denotes the elongation rate by the RNA polymerase in nucleotides per hour, l_{mRNA} denotes the mRNA length in nucleotides, $Gene$ denotes the gene concentration, k_m denotes the plasmid saturation coefficient, and P denotes the promoter activity. The mRNA and protein sequence of CAT was determined from literature. The promoter activity was formulated following Moon et al. for synthetic circuits as:

$$P = \frac{K_1}{1 + K_1} \quad (11)$$

where K_1 denotes the state of T7 RNA polymerase binding. The translation rate was formulated as:

$$w_{TL} = K_P Ribo \left(\frac{v_{Ribo}}{l_{Protein}} \right) mRNA_{SS} \quad (12)$$

where K_P denotes the polysome amplification constant, $Ribo$ denotes the ribosome con-

centration, v_{Ribo} denotes the elongation rate of the ribosome in amino acids per hour, $l_{Protein}$ denotes the number of amino acids in the protein of interest, and $mRNA_{ss}$ denotes the mRNA concentration at steady state, equal to the transcription rate divided by the degradation rate of mRNA.

An ensemble of 100 sets of flux distributions was calculated for three different cases: unconstrained, constrained by transcription/translation rates, and constrained by transcription/translation rates and experimental measurements. For the unconstrained case, all rates were left unbounded, except the specific glucose uptake rate. An ensemble of flux distributions was then calculated by randomly sampling the maximum specific glucose uptake rate from within a range of 30 to 40 mM/h, determined from experimental data. For the case constrained by transcription/translation rates, an ensemble was generated by randomly sampling RNAP polymerase levels, ribosome levels, and elongation rates in a physiological range determined from literature. RNA polymerase levels were sampled between 60 and 80 nM, ribosome levels between 7 and 16 μ M, the RNA polymerase elongation rate between 20 and 30 nt/sec, and the ribosome elongation rate between 1.5 and 3 aa/sec [29, 48]. For the case constrained by transcription/translation rates and experimental measurements, the lower and upper bounds on the fluxes for the data-informed metabolites were sampled within the range given by the experimental noise. This included the data for glucose, organic acids, energy species, and amino acids; CAT was not constrained by experimental data, but by the transcription/translation rates as stated above.

Competing interests

The authors declare that they have no competing interests.

Author's contributions

J.V and A.Y directed the study. R.T, H.J and J.C conducted the cell culture measurements. J.V and W.D developed the reduced order HL-60 models and the parameter ensemble. W.D analyzed the model ensemble, and generated figures for the manuscript. The manuscript was prepared and edited for publication by W.D, A.Y and J.V.

Acknowledgements

We gratefully acknowledge the suggestions from the anonymous reviewers to improve this manuscript.

Funding

This study was supported by a National Science Foundation Graduate Research Fellowship (DGE-1333468) to N.H and by an award from the US Army and Systems Biology of Trauma Induced Coagulopathy (W911NF-10-1-0376) to J.V for the support of M.V.

Fig. 1: Central carbon metabolism in the presence (top) and absence (bottom) of allosteric control, including glucose (substrate), CAT (product), and intermediates, as well as total concentration of energy species. Best-fit parameter set (orange line) versus experimental data (points). 95% confidence interval (blue shaded region) and 95% confidence interval of the mean (gray shaded region) over the ensemble of 100 sets.

Fig. 2: Energy species and energy totals by base in the presence of allosteric control. Best-fit parameter set (orange line) versus experimental data (points). 95% confidence interval (blue shaded region) and 95% confidence interval of the mean (gray shaded region) over the ensemble of 100 sets.

Fig. 3: Amino acids in the presence of allosteric control. Best-fit parameter set (orange line) versus experimental data (points). 95% confidence interval (blue shaded region) and 95% confidence interval of the mean (gray shaded region) over the ensemble of 100 sets.

Fig. 4: Log of cost function across 37 datasets for data-trained ensemble (blue) and randomly generated ensemble (red, gray background). Median (bars), interquartile range (boxes), range excluding outliers (dashed lines), and outliers (circles) for each dataset. Median across all datasets (large bar overlaid).

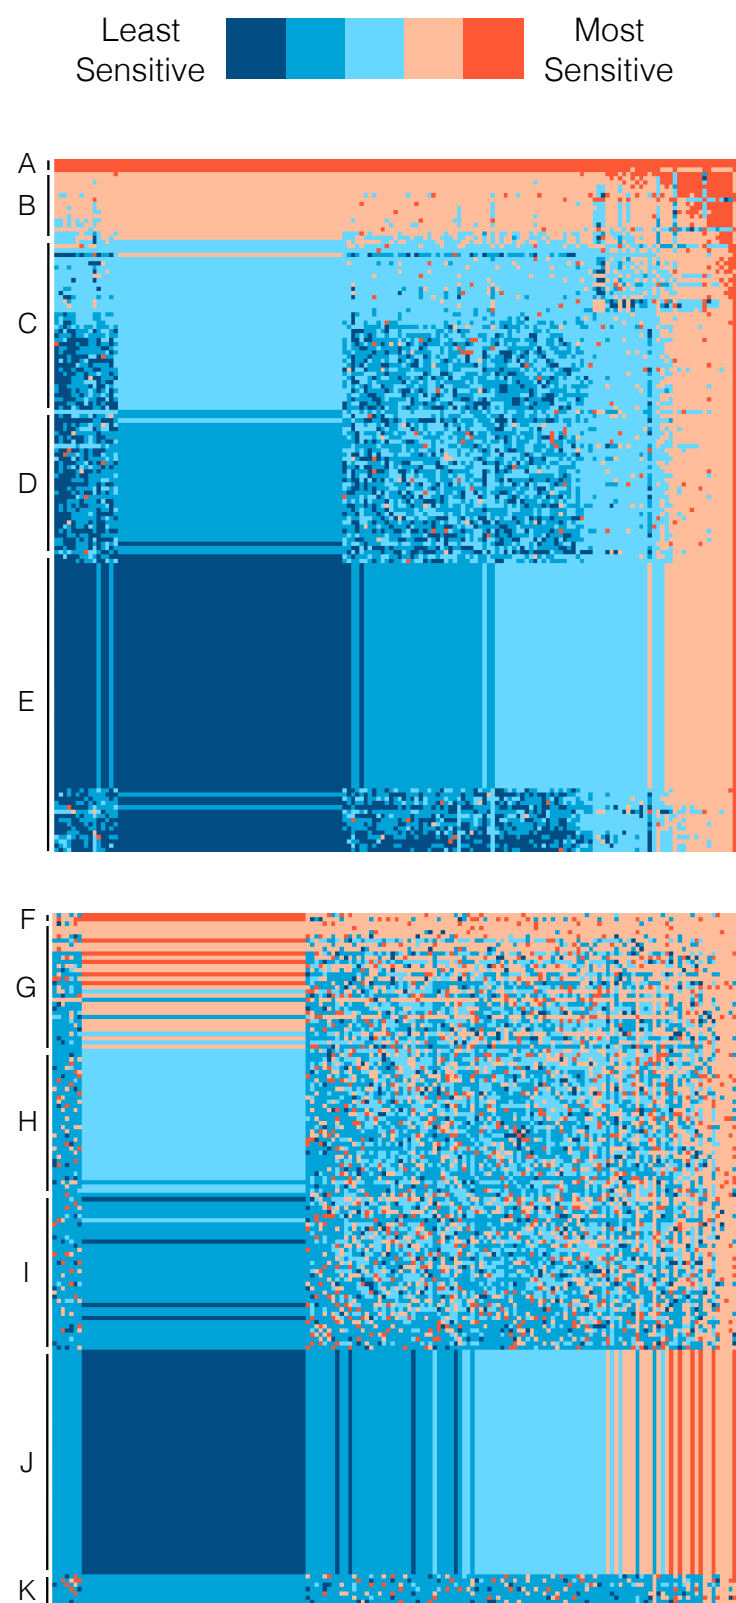

Fig. 5: Normalized first-order and pairwise sensitivities of CAT production (top) and system state (bottom) to maximum reaction rates.

Fig. 6: The effect of oxidative phosphorylation on glucose uptake, CAT production and CAT carbon yield. A. 95% confidence interval of an ensemble for glucose concentration versus time for no knockouts (blue shaded region), *cyd* knockout (green shaded region), and *nuo* knockout (red shaded region). B. 95% confidence interval of an ensemble for CAT concentration versus time for no knockouts (blue shaded region), *cyd* knockout (green shaded region), and *nuo* knockout (red shaded region). C. CAT carbon yield for 5 different cases of oxidative phosphorylation: no knockouts (blue), *cyd* knockout (green), *nuo* knockout (red), *app* knockout (light grey), and a combination of *cyd*, *nuo*, *app* knockouts (dark grey).

Fig. 7: Sequence-specific flux balance analysis of CAT production and yield. A. 95% confidence interval of the ensemble (light blue region) for CAT concentration versus time. B. Theoretical maximum carbon yield of CAT calculated by ssFBA for three different cases: unconstrained except for glucose uptake (black), constrained by transcription/translation (TX/TL) rates (grey), and constrained by transcription/translation (TX/TL) rates and experimental measurements where available (light grey). Error bars represent standard deviation of the ensemble.

Fig. 8: Flux profile for glycolysis, pentose phosphate pathway, Entner-Doudoroff pathway, TCA cycle, NADPH/NADH transfer, and oxidative phosphorylation. Sequence-specific FBA flux value (mean ± standard deviation) across ensemble for 1 hr, normalized to glucose uptake flux. Flux distribution for three different cases: unconstrained except for glucose uptake (top row), constrained by transcription and translation rates (second row), and constrained by transcription, translation rates and experimental measurements where available (bottom row).
